Diagnosis and management in Rubinstein-Taybi syndrome: first international consensus statement

ABSTRACT
Rubinstein-Taybi syndrome (RTS) is an archetypical genetic syndrome that is characterised by intellectual disability, well-defined facial features, distal limb anomalies and atypical growth, among numerous other signs and symptoms. It is caused by variants in either of two genes (CREBBP, EP300) which encode for the proteins CBP and p300, which both have a function in transcription regulation and histone acetylation. As a group of international experts and national support groups dedicated to the syndrome, we realised that marked heterogeneity currently exists in clinical and molecular diagnostic approaches and care practices in various parts of the world. Here, we outline a series of recommendations that document the consensus of a group of international experts on clinical diagnostic criteria for types of RTS (RTS1: CREBBP; RTS2: EP300), molecular investigations, long-term management of various particular physical and behavioural issues and care planning. The recommendations as presented here will need to be evaluated for improvements to allow for continued optimisation of diagnostics and care.

INTRODUCTION
Rubinstein-Taybi syndrome (RTS) (MIM (Mendelian Inheritance in Man) #180849; #613684; #610543) is a multisystem disorder with physical, cognitive and behavioural characteristics, which can be caused by variants in two genes that regulate transcription via chromatin remodelling. The condition is named after the US paediatrician Jack Rubinstein and Iranian radiologist Hooshang Taybi who described seven affected infants in 1963.1 There are >800 publications on RTS and related topics. Within the framework of the European Reference Network Ithaca a group of international experts recognised the importance of equal practices regarding diagnostic procedures and care for individuals with RTS. To address this issue, an international consensus group was established, which performed a literature review, evaluated data critically, formulated conclusions and held a face-to-face meeting in the presence of patient group representatives. This has led to the present series of guidelines for diagnostics and care for individuals with RTS. For Methods see online supplemental materials.

CLINICAL DIAGNOSTIC CRITERIA
Definition
The goal of defining an entity is that affected individuals and their caregivers who face similar signs, symptoms and health problems, can meet one another, share knowledge, emotions and experiences about the disorder, support one another, and, this way, facilitate care and research. So the essence of a definition is to allow grouping together individuals with the same diagnosis.

Currently, variants in the genes CREBBP and EP300 are known to cause RTS.4 5 One may argue that the diagnosis of RTS should be based on these molecular findings and clinical diagnostic criteria are no longer needed. Several issues argue against this: there are individuals with a phenotype classically fitting RTS, but without detectable cytogenetic or molecular anomaly; there are individuals with a genuine variant in CREBBP or EP300 but with a phenotype different from the RTS phenotype,4 which can have major consequences in counselling patients and families; there are individuals with
We used the scored features as available, to avoid a bias. Signs present in at least 75% of either of the two groups were accepted as being sufficiently characteristic of the condition. In addition, we added three features with a lower frequency but which are highly specific for RTS: (1) radially deviated thumbs; (2) keloid formation; and (3) maternal pre-eclampsia. We considered adding talon cusps to these criteria but refrained from doing so as this sign is not yet present in the age group during which typically a diagnostic question arises. When developing the scoring system, it was observed that the presence or absence of the sign ‘long eyelashes’ did not contribute to sensitivity, and given the low intra-observer reliability of this feature it was excluded from the scoring criteria. Furthermore, the features known to be highly specific for RTS (radially deviated thumbs; typical smile; cleft palate below alae nasi, maternal pre-eclampsia keloids) were given a higher weighted value in the scoring system to reflect their diagnostic importance. Features were then subdivided into Cardinal Features, which we considered to be essential for RTS, and Suggestive Features, which are present less frequently but should raise suspicion for RTS (table 2; figure 1). Subsequent discussion of these criteria allowed consensus for the clinical diagnostic criteria, based on the presence of both Cardinal and Suggestive Features (online supplemental R1). If an individual either a CREBBP or an EP300 variant of uncertain pathogenicity, and whose phenotype resembles RTS only to a limited extent, leaving it uncertain whether or not the variant is causative for the phenotype; there are many countries worldwide in which the availability of molecular studies is limited, and in which caregivers have to rely on a clinical diagnosis for counselling. For these reasons, we concluded that a clinical definition of the RTS phenotype is still needed and will remain needed. There is no widely accepted set of clinical diagnostic criteria for RTS. We used the largest published set of data on individuals with RTS and either a CREBBP (n=308) or an EP300 variant (n=52), to determine the sensitivity of signs and symptoms (table 1).

Cardinal Score is positive only if two of the four groups score positiscores ve and also at least either skeletal or craniofacial scores positive

Definitive clinical diagnosis of Rubinstein-Taybi syndrome: Score ≥12 and positive cardinal score.

Likely clinical diagnosis of Rubinstein-Taybi syndrome: Score 8–11 and positive cardinal score. This score warrants molecular analyses of CREBBP and EP300.

Possible clinical diagnosis of Rubinstein-Taybi syndrome: Score 5–7 and negative cardinal score. This score warrants molecular analyses of CREBBP and EP300.

Unlikely clinical diagnosis of Rubinstein-Taybi syndrome: Score 0–4 and negative cardinal score. Further studies for other aetologies indicated.
Clinical guidelines

scores 12 or higher, including meeting a score for the Cardinal Features, the diagnosis of RTS can be clinically confirmed irrespective of the results of molecular testing. A score of 8–11 including a positive score for the Cardinal Features indicates a likely diagnosis of RTS which requires further confirmation by molecular testing. A score of 5–7, with or without a Cardinal Feature, indicates that the diagnosis of RTS is still possible and molecular studies are indicated. A score of 0–4 indicates that the diagnosis is unlikely, and other explanations of the phenotype should be explored.

We realise that the presence of unusual signs and symptoms is not incorporated in the score as a negative feature. Still, these should always also be taken into account. Especially the presence of an unusual sign or symptom in someone with a score indicating a likely or definitive diagnosis of RTS should lead to considering the presence of a co-existing second (possibly Mendelian) disorder. In addition, in scoring signs, especially low-hanging columella, the ethnic background should be taken into account as in some ethnicities a low-hanging columella is a common variant. If uncertainty remains it is often useful to evaluate both parents and other relatives as well (online supplemental R2). Lastly, in the first months of life delayed development and disturbed postnatal growth may not yet present and a definitive score may be only possible at an age when this can be reliably ascertained.

Subsequently, we evaluated whether the set of diagnostic features allowed establishing the diagnosis reliably in a group of 100 individuals with molecularly confirmed RTS, that had not been part of the group of patients on which the criteria were built (online supplemental table S1). All individuals scored 5 or higher, indicating none would have been missed as having RTS based on clinical criteria (complete sensitivity). Only seven patients scored in the group Possibly RTS, others scored in the group Likely RTS (n=38) or Definitively RTS (n=55). Furthermore, we evaluated whether 45 individuals with a specific group of pathological CREBBP or EP300 variants, who have been considered to have a separate entity (Menke-Hennekam syndrome (MKHK); MIM #618332 / #618333), would be correctly distinguished from RTS (online supplemental table S1). Results showed that none scored as definitive or likely RTS, as possibly RTS and 36 as unlikely RTS, so the entities could correctly be discerned. To determine the specificity, we reasoned that three entities that may resemble RTS and are not uncommon, that is, Floating Harbour syndrome (FHS; MIM #136140) (n=45), Wiedemann-Steiner syndrome (WDSTS; MIM #605130) (n=46) and Cornelia de Lange syndrome (CDLS; MIM #122470) (n=100), should be reliably discerned from RTS based on the set of weighted clinical features (online supplemental table S2). Results showed that none of the individuals with FHS and CDLS fulfilled the criteria for a definitive diagnosis of RTS, but one of the patients with WDSTS had such a score. In addition, one of the patients with WDSTS had a score within the Likely RTS group but was found by the present authors to have a classical RTS facial gestalt. This has to be expected as RTS is a chromatinopathy, and variants in other genes acting in the same pathway are likely to have consequences for the phenotype as well and rarely may even alter the phenotype significantly. Further studies to explain this unusual phenotype are planned. Furthermore, 8 of the 46 WDSTS individuals, and 1 of the 100 CDLS individuals fulfilled the criteria for Likely RTS, indicating that specificity was very high, but not complete. Due to the overlap in function of the genes involved in the four entities, this is to be expected. The results are in agreement with our joint clinical experience that, infrequently, discrimination between RTS and WDSTS based on clinical criteria can be extremely difficult. This happens less frequently in patients with CDLS and in FHS, but the phenotypic overlap is still marked. Obviously, this has consequences for the molecular analyses in someone with such scores (see Molecular diagnostic criteria). We realise that prospective studies will be needed to determine more reliable specificity and sensitivity. In addition,
**Clinical guidelines**

such studies should include individuals of non-European descent, to evaluate whether the scoring system will be equally valid as in individuals of European descent.

**Severity score**

A major issue for families, especially at the time of diagnosis, is an indication of the severity of RTS. No severity score for RTS has been published to date. In our opinion a comparison and weighting of the severity and influences that various signs and symptoms have on the quality of life of an affected individual can only be made by the affected individuals and their families, and not just by physicians. We suggest that a group of family members should be facilitated to indicate which set of physical, cognitive and behavioural issues influence the life of individuals with RTS most. Ideally, such criteria should be stratified according to the nature of the molecular genetic cause (online supplemental R3).

**MOLECULAR DIAGNOSTIC CRITERIA**

RTS has been subdivided into type 1 (RTS1; OMIM #180849) and type 2 (RTS2; OMIM #613684) associated with heterozygous pathogenic variants or re-arrangements in the genes CREBBP and EP300, respectively, typically leading to haploinsufficiency. Both genes encode paralogous transcriptional co-activators with lysine acetyltransferase activity. The proteins CBP and p300 play a crucial role in transcription initiation by acting as a bridge, linking transcription factors to the transcription machinery, and through acetylation of histones (figure 2).

**Mutation spectrum**

Variants in CREBBP and EP300 have been identified in 55–75%, and 8–11%, of individuals with RTS, respectively, of whom 2–3% have deletions of the complete gene. In 5–20% no molecular anomaly can be detected (online supplemental R4). To date, over 500 CREBBP and over 100 EP300 pathogenic variants are known, distributed along all 31

---

**Figure 2**  Structures and functions of CBP/p300. (A) The proteins CBP and p300 are composed of 2442 amino acids (AA) and 2414 AA, respectively, with 58% of sequence similarity within their domains. The various domains are represented by their position in the AA sequence: N-terminal nuclear receptor interaction domain (NRID or RID), cysteine-histidine rich region 1 (C/H1) containing the transcriptional adapter zinc finger 1 (TAZ1), kinase-inducible domain (KID) interacting domain (KIX), Bromodomain, C/H2 containing a plant homeodomain (PHD), lysine acetyltransferase domain (KAT), C/H3 containing the zinc finger (ZZ) and TAZ2 domains and interferon-binding transactivation domain (IBiD). The Menke-Hennekam syndrome (MKHKS) region corresponds to the location of the missense variants leading to the MKHKS. (B) CBP and p300 act as transcriptional co-activators of target genes by different mechanisms: (1) Binding function by facilitating the physical and functional interactions of TF; (2) scaffolding function allowing the recruitment of TF and in particular CREB; (3) KAT function by catalysing the transfer of acetyl groups on lysine residues of both histone tails and non-histone proteins such as the RNApolII complex and TF. Ac, acetyl group; TBP, TATA binding protein; TF, transcription factors. Adapted from a study by Van Gils et al.15
exons (figure 3). Several recurrent CREBBP variants have been reported, ~50% of missense variants are localised in the KAT domain, and recurrent rearrangements occur between introns 1 and 2 of CREBBP due to the high frequency of repeated or palindromic sequences in this region.16 17

Genotype-phenotype correlation

Individuals with RTS1 and RTS2 both may show the classical phenotype but this may also vary. Individuals with RTS2 demonstrate in general less marked typical facial characteristics, no radial deviation of the thumbs, have infrequently keloids and a higher average cognitive level.5 13 14 However, maternal precocious intrauterine growth retardation and microcephaly are more common in RTS2 compared with RTS1.3

The type and site of variants in CREBBP and EP300 do not associate with a specific phenotype with respect to external morphology, malformations, cognition or behaviour.5 11 13 18 19 (online supplemental R5). The exception is formed by missense variants between the end of exon 30 and the beginning of exon 31 of both CREBBP and EP300, which both lead to a phenotype that differs from RTS (table 1) and has been designated as MKHK (OMIM #618332, #618333).4 20 These missense variants hypothesised to affect specifically the binding properties of the ZNF2 (zinc finger, ZZ type) and ZNF3 (zinc finger, TAZ type) domains to different CBP partners by affecting their own folding.21 22

RTS shows broad phenotypic overlap with other Mendelian disorders affecting the structure of chromatin genomewide called ‘chromatinopathies’, such as FHS (OMIM #136140), CDLS (OMIM #122470, #300590, #610759, #614701, #300882, #608749), WDSTS (OMIM #605130), Kabuki syndrome (OMIM #147920, #300867), genitopatellar syndrome (OMIM #606170), Biesecker-Young-Simpson syndrome (OMIM #603736) and Gabriele-de Vries syndrome (OMIM #617557).

Diagnostic approach

There are two main entry points for molecular genetic testing in RTS: clinical suspicion of RTS or no clinical suspicion (figure 4). If clinical presentation suggests RTS, the first-line tests are either targeted analysis of CREBBP and EP300 by Sanger sequencing and Multiplex Ligation-dependent Probe Amplification (MLPA) or by high throughput analysis (array Comparative Genomic Hybridisation (aCGH); whole-exome sequencing (WES) if accessible). If RTS is not suspected in an individual with intellectual disability and/or malformations, the first tier is high throughput analyses (aCGH; WES or whole-genome sequencing). Evaluation of variant should be performed using the ACMG (American College of Medical Genetics and Genomics) classification.23 Additional RNA studies are needed in case of unknown splicing variants. Suspicion of somatic mosaicism should be confirmed in more than a single tissue (buccal swab; bladder epithelium cells; skin biopsy). The phenotype should be re-evaluated after the identification of a (possibly) pathogenic variant to confirm that the molecular finding fits the clinical phenotype. If targeted analyses yield negative results and high throughput analyses are not available, the diagnosis remains dependent on the clinical phenotype and a definitive diagnosis may not be possible.

If the clinical diagnosis cannot be confirmed molecularly, molecular analyses yield a variant of unknown significance, or the phenotype does not fit the molecular finding, analysis of a genome-wide methylation pattern (epigenetic signature) can be performed as individuals with RTS have a specific pattern.24

If all studies are negative, one should consider other diagnoses. Still, currently, not all molecular mechanisms leading to RTS are known, and if the clinical diagnostic criteria for RTS are met (see
Clinical guidelines

Clinical diagnostic criteria), the diagnosis of RTS remains the standard in guiding management and follow-up of the patient.

Recurrence risk
RTS is inherited as an autosomal dominant trait and occurs de novo in over 99% of patients. However, familial occurrence does occur, either if a parent is relatively mildly affected or due to somatic or germ-line mosaicism. To date, eight instances of somatic or germ-line mosaicism and seven instances of parent-to-child transmission have been described in over 2000 reported affected individuals, indicating the empirical recurrence risk is 0.5–1%. The recurrence risk for offspring of an affected individual is 50%, although it may be lower due to a spontaneous miscarriage.

Prenatal diagnosis
Without a positive family history, the prenatal diagnosis of RTS is only infrequently made as there are few reliable antenatal signs. Truly detailed three-dimensional ultrasonography may allow suggestive facial characteristics, but the morphology of the extremities, and specifically the radially deviated thumbs, are the main diagnostic handles. Additional findings that may be helpful are intrauterine growth retardation, polyhydramnios, underdevelopment of the cerebellum and gallbladder anomalies.

The main reason to perform prenatal diagnostics for RTS is the birth of a previous child with RTS in the family. If a causative variant in CREBBP or EP300 has been detected, reliable molecular prenatal diagnostics can be performed in samples obtained by chorionic villus sampling or amniocentesis, or in embryonic cells obtained by in vitro fertilisation.

Prenatal testing in families without a previous child with RTS and a known pathogenic variant, by non-invasive cell-free fetal DNA screening, is not advocated, as an interpretation of the pathogenicity of variants detected this way may be extremely difficult. This limits the validity and informative value of the prenatal testing and may cause ethical issues for the families in deciding whether or not a pregnancy should be continued. Any prenatal testing needs to be discussed carefully with the couple before the procedure and should take into account the differences in perspective of couples and national legislation.

NEONATAL CARE
Recognition
86% of children present within the first month of life and 70% of these on the first day of life; prolonged hospital admission after birth was reported in 61%. Early recognition of RTS may help identify complications and assist families to cope. The typical facial features of RTS evolve with time. The characteristic appearance in the neonatal period differs somewhat as it is mainly characterised by a prominent forehead with haemangiomas (‘stork-bite naevus’) in the glabella region, (apparent) hypertelorism, epicanthi and at that age up-slanting palpebral fissures. The nasal bridge tends to be straight, the tip short and upturned, and the nasal septum is not or only slightly extending beyond the alae. A small mouth, highly arched palate and small mandible are also present. Additional features can be unusually thick, black hair, a large anterior fontanelle and long eyelashes. Newborns with a variant in EP300 tend to have a less obvious phenotype. The distal limb anomalies are the most characteristic of RTS in the neonatal period and are similar to those at...
an older age (see Clinical diagnostic criteria). Cryptorchidism is common.

Feeding
Neonatal feeding difficulties are common (71–80%), due to swallowing incoordination, poor nipple grasp, hypotonia and gastro-oesophageal reflux. Nutritional supplementation including gastric tube feeding is required in 40% of cases, as are occasionally percutaneous tubes, but most feeding challenges will have resolved within the first year of life. Should feeding difficulties persist, additional professionals should be consulted (see Gastroenterology). Still, half of the mothers report a sufficient suck and were pleased with their breastfeeding experience. Adequate breastfeeding instructions, proper positioning and ongoing encouragement are indicated (online supplemental R8).

Birth parameters
At birth most infants fall within the normal range for weight, length and head circumference, although a higher incidence of microcephaly and growth restriction has been reported in infants with EP300 variants, possibly related to the frequently occurring pre-eclampsia. There is no increased risk of preterm birth. The use of RTS-specific growth charts is encouraged to monitor growth adequately (online supplemental R9).

Systemic manifestations
The various systemic manifestations of RTS are described elsewhere in the guidelines. The work-up of every newborn with suspected or confirmed RTS should include ophthalmological exams (glaucoma; coloboma); cardiac assessment (malformations); and renal ultrasound (malformations) (online supplemental R10). Obviously, further care such as the baseline newborn hearing screening and vaccinations should be performed as per the general population.

ENDOCRINOLOGY
Hypoglycaemia
Transient hypoglycaemia occurs with a low frequency in newborns with RTS and responds well to usual management schemes (online supplemental R11). Hypoglycaemic hyperinsulinism (HH) is very rare, may occur after birth or in the first years of life, is sometimes associated with concurrent illness, and can be transient or permanent. It has mainly been described in children with EP300 variants. Early diagnosis and treatment of HH is crucial to avoid permanent brain damage. Treatment is as in the general population: frequent enteral feeding, continuous glucose infusion and diazoxide. Usually, specialist consultation is needed.

Growth
Postnatal growth retardation is a hallmark of RTS. Usually within months after birth, the length, weight and head circumference drop from normal values to −2SDS. Neither boys nor girls show a pubertal growth spurt, which contributes to a subsequent average adult height of −3SDS for both men and women. The use of growth charts specific for RTS, based on molecularly confirmed patients, facilitates adequate monitoring of growth (online supplemental R9). Growth hormone (GH) deficiency is infrequent but has been reported in few individuals, in whom GH therapy resulted in an increase in height SDS. Every child in whom growth differs markedly from the growth pattern of the dedicated growth charts needs to be evaluated for GH deficiency (online supplemental R12). If present, treatment is as in the general population. Prepubertal boys and girls may develop an unusual body shape due to increased fat tissue around the abdomen and hips, which disappears in puberty in boys, but often persists throughout life in girls.

Puberty
The timing of puberty and the development of secondary sex characteristics usually falls within normal limits. The mean age of onset of puberty was 12.2 years, with a mean age of menarche at 13.6 years. There is no indication that fertility has decreased, although formal studies are lacking. About 25% of adult males and females with RTS are sexually active. Sexual education should be proposed according to the level of emotional and cognitive functioning, and contraceptive options are recommended as in the general population taking the level of developmental functioning into account (online supplemental R13).

GASTROENTEROLOGY
Malformations of the gastrointestinal tract such as a duodenal web and malrotation occur at a low frequency in newborns with RTS, although the frequency of the malrotation may be higher than in the general population. Symptomatology is similar in newborns without RTS and should be managed as in the general population.

Feeding problems are very frequent at birth and may remain present for a prolonged period of time. Oral feeding is preferred if it is safe and feasible, while tube feeding may be needed and a gastrotomy for long-term use. The involvement of dieticians is often helpful (online supplemental R14). Although feeding problems are in part explained by recurrent respiratory infections and hypotonia, also gastro-oesophageal reflux (GOR) may play a role. Limited GOR occurs in all healthy infants and children; if causing excessive symptoms it is referred to as GORD disease (GORD). The symptomatology of GORD may vary widely, from feeding problems, dental enamel erosions and recurrent pneumonias to restlessness and poor sleep. The pathogenesis remains uncertain. GORD (D) should be differentiated from excessive regurgitation after feeds in otherwise asymptomatic infants, which is usually indicated as infant rumination syndrome. Extremely rarely, eosinophilic oesophagitis may develop. Given the lack of evidence for the management of GORD specifically in RTS, management of GORD should be as in the general population, thickening of food and reassurance of parents as a first step. If symptoms persist, an initial trial with PPI (Proton Pump Inhibitors) treatment can be considered. If problems continue, further evaluation should be considered. If a PPI trial improves symptomatology, this does not conclusively prove acid-related GORD. Long-term use of PPI may cause side-effects, thus in successful PPI trials individuals should undergo weaning trials regularly (eg, after 6 months and yearly thereafter) to evaluate the utility of continuing PPI treatment, while mitigating rebound effects by dose tapering. If symptoms persist or recur, additional testing, such as pH-impedance testing and/or endoscopy can be considered (online supplemental R15). Fundoplication and other surgical interventions are not recommended in an early phase of management, as these have a relatively high failure rate, commonly cause complications and can induce dysphagia and subsequent feeding problems; it should be reserved for patients with proven GORD unresponsive to optimal nutritional and medical therapy. Fortunately, complications of long-term GORD such as Barrett’s oesophagus are rare in RTS, and oesophageal cancer has not been reported.
Constipation is extremely prevalent in RTS across all age groups throughout the lifespan. The cause remains unknown, Hirschsprung disease or other identifiable aetiologies do not occur more frequently than in the general population. Additional investigations are only indicated if symptomatology suggests an underlying disease. Long-term treatment with increased dietary fibres and fluid intake, and oral osmotic laxatives remain the cornerstone of treatment (online supplemental R16). In severe cases, stimulant laxatives may be added, and further management schemes are as in the general population.

**CARDIOLOGY AND PULMONOLOGY**

**Cardiovascular system**

Congenital heart defects (CHDs) occur in 30% of cases, without a genotype–phenotype correlation. The reported differences in incidence according to ethnicity can be explained by ascertainment bias and differences in methodology. The typical CHDs are patent ductus arteriosus, persistent foramen ovale and atrial and ventricular septal defect. Individuals with a CHD do not have a higher rate of other malformations or are associated with impaired cognitive function.

The cardiovascular system should be evaluated at diagnosis, including cardiac sonography (online supplemental R17). Treatment is as in the general population, including endocarditis prophylaxis as indicated. Surgery is needed in 15–22% of patients. CHDs do not cause unexpected complications in adults.

Cardiovascular problems typical for the general adult population occur in adults with RTS at a lower frequency. Hypertension is reported in 10% of adults, and surveillance and treatment are as in the general population (online supplemental R18).

**Pulmonary system**

Mild respiratory distress in the first hours of life is common in RTS neonates. Treatment is only needed if other risk factors such as prematurity are present. Upper respiratory infections are common (see **Immunology**). Infections of the lower respiratory system are uncommon, and are explained by feeding problems, microaspirations and gastro-oesophageal reflux. Exceptionally, immunodeficiency may play a role; the reported higher frequency of lower respiratory infections was caused by a study bias. In case of recurrent pneumonia with wheezing, hoarseness or stridor, the patient should first be evaluated for gastroesophageal reflux. CHDs do not cause unexpected complications in adults.

Symptoms depend on location and size and may include visual field loss, reduced vision and photophobia. There is no curative therapy, but sometimes glare can be reduced by wearing sunglasses.

Retinal abnormalities occur frequently, but are often subtle, so may go unnoticed, without severe loss of vision, except for macular degeneration secondary to high myopia (online supplemental R21). Evidence may be present in the abnormal distribution of pigmentation in the macula and a subnormal electroretinogram. In some patients, the abnormal aspect of the macula is caused by foveal hypoplasia (Van Genderen, unpublished).

### Functional anomalies

Visual impairment (best corrected binocular visual acuity <6/18) occurs in 20% of individuals, and typically is caused by anatomical abnormalities. Bilateral severe anomalies may lead to infantile nyctagmus because of decreased sensory input from birth. Retractive errors and strabismus are very common, both occurring in 50–75% of individuals, and may change rapidly with age indicating the need for frequent controls, especially under 5 years of age (online supplemental R21). In young children, high retractive errors need correction to prevent amblyopia. Children may however refuse to wear glasses if improvement of vision is not immediately evident. Gradual introduction in situations in which the child benefits most from
glasses may allow the child to get accustomed to wearing spectacles (online supplemental R22).

Treatment of strabismus to prevent amblyopia is as in the general population, provided the affected eye has no congenital anomaly that inhibits amelioration of vision.

Photophobia is common due to cataracts, glaucoma or trichiasis. Treatment is by treating the cause. Photophobia secondary to coloboma or retinal dysfunction can be ameliorated by shielding the eyes from direct (sun) light or wearing sunglasses.

OTOLARYNGOLOGY AND ANAESTHESIOLOGY

Hearing
The typical facial characteristics in individuals with RTS include a small chin and small oral cavity which can result in airway difficulties and, together with gastro-oesophageal reflux, can result in complications such as recurrent middle ear infections. Conductive, sensorineural and mixed hearing loss may result. Regular auditory evaluation is therefore recommended (online supplemental R23).

Sleep
Abnormal facial anatomy and increased collapsibility of the laryngeal walls predispose individuals with RTS to higher rates of sleep-disordered breathing and OSA. Sleep disorders are frequent in children, and occur in 62% of adults. OSA is typically characterised by snoring and excessive daytime sleepiness and affects 25% of adults with RTS. If present in children the facial anatomy is often markedly abnormal and accompanied by obesity, hypotonia and adenotonsillar hypertrophy. As with the general population, management should take into account the various causal factors as well as potential difficulties in treating both children and adults with RTS (online supplemental R24). Assessment of the sleep patterns using a validated questionnaire, such as the Sleep Disturbance Scale for Children, may offer information on both sleep patterns and response to therapy (online supplemental R25). Prior to a major surgical intervention, polysomnography should be considered.

Management of sleep disorders is aimed at implementing healthy sleep practices, particularly position during sleep, behavioural strategies and the use of and education on pharmacological interventions. Melatonin should be used appropriately in individuals with specific types of insomnias and sleep rhythm disturbances.

Anaesthesiology
Approximately 48% of adults with RTS require surgery at least once, with half of those requiring two or more surgeries during their lifetime. Children with RTS are no exception as they receive a higher fraction of anesthetics relative to their age-matched cohorts. As a result of the multisystemic manifestations of RTS, anaesthesiologists should be prepared to provide a tailored anaesthetic for this population (online supplemental R26).

Premedication and behavioural therapy support may prove beneficial in the preoperative setting. A single case series described complications such as cardiac arrhythmias associated with intraoperative administration of atropine and succinylcholine, but other studies have shown the safe and efficacious use in RTS and this is also our joint personal experience. The altered facial anatomy may make mask ventilation, laryngoscopy and intubation challenging, and coupled with positioning limitations that may be present due to scoliosis, kyphosis, hypermobility and obesity, may warrant the use of video-laryngoscopy or fiberoptic intubation. Rarely, transnasal placement of a nasopharyngeal airway or nasogastric tube is inhibited due to narrow or atretic choanae.

Intraoperative management of ventilation and postextubation care can be complicated by the presence of laryngotracheomalacia and augmented airway reactivity. In the immediate postoperative period, opioid use, while not contraindicated, should be used judiciously to prevent exacerbation of obstructive symptoms and hasten potential apnoeas. The perioperative use of analgesic and anxiolytic adjuncts such as non-steroidal anti-inflammatory drugs, acetaminophen and dexmedetomidine are encouraged, if not contraindicated secondary to other comorbidities or surgical considerations. Initiation of transient, non-invasive positive airway pressure may be helpful. Secondary to the elevated risk of complications with anaesthesia and airway manipulation, particular efforts should be made to bundle non-emergent procedures into a single anaesthetic to mitigate potential morbidity (online supplemental R27).

DERMATOLOGY

The main skin problem in RTS is the propensity to develop keloid. Keloids are non-malignant fibrous growths resulting from an abnormal response to skin injuries or inflammation that extend beyond the borders of the original wound. The pathogenesis of keloids is thought to involve multiple patient-specific factors (genetics, age, hormones, ethnicity), and environmental factors (trauma, surgery, inflammation) which collectively stimulate wound healing and persistent inflammation. Spontaneous keloid development occur only in genetic syndromes, raising the question whether they are truly spontaneous, or whether unrecongnised triggering environmental factors occur.

RTS is the syndrome considered to have the highest risk of keloid development. The frequency of Dutch and UK RTS individuals developing keloids was 24%. While keloids are most frequently occurring in association with CREBBP variants, among 10% of individuals with EP300-related disease develop such changes. Compared with the general population keloids develop earlier in life in individuals with RTS and increase with age: up to 60% was reported in a cohort of adults. Up to 100 keloids have been recorded in the same individual. In RTS keloids are most frequently seen on the shoulders and chest. Development of keloids is not associated with other traits of the phenotype within RTS.

Apart from aesthetic issues, keloids cause pain, itching and reduced mobility of the involved region, thus seriously affecting the quality of patients’ lives (online supplemental R28). Prevention is difficult and keloids may be unavoidable as minimal trauma such as rubbing of clothes may be sufficient to induce keloid formation. There are no standardised treatment protocols for keloids in individuals with RTS. Therapy options include repeated intra-lesion steroid injections, laser therapy, compression, local radiation, cryotherapy and surgery, either individually or in combination, but no treatment is fully satisfactory, and the recurrence rate remains high. There is no detectable association between keloids and cancer risk, suggesting different aetiologies or pathogeneses.

Another skin problem in RTS occurring in 17% of a series of molecularly proven Dutch cases are multiple pilomatrixomas: benign skin tumours derived from hair matrix, often harbouring activating mutations of beta-catenin. These skin-coloured, red or white lesions typically occur on the head and neck in children and adolescents, but do occur elsewhere and may arise at older ages as well. Pilomatrixomas typically calcify, causing them to feel like hard lumps. They may coexist with keloids.
to keloids there are often multiple pilomatricomas, and puberty may act as a triggering factor. Complete surgical excision has been recommended, but others suggested surgical removal only in case of discomfort (online supplemental R29).

Ingrowing nails occur regularly in both fingers and toes, especially in the partially duplicated thumbs and halluces, and may cause pain and skin infections. Adequate instructions regarding nail care and avoiding narrow shoes may prevent ingrowing nails (online supplemental R30). Treatment is as in the general population. Further skin findings in RTS are congenital generalised hypertrichosis, both in individuals with CREBBP and EP300 variants, apparently more frequent in individuals from Latin America and the Middle East and less frequently in those from Africa. Usually, it becomes less marked with age. Other changes are angiomas, melanocytic naevi, white papulae on the trunk and limbs, supernumerary nipples and sometimes lentigines and café-au-lait spots.

UROGENITAL SYSTEM
Urinary tract
Urinary tract anomalies occur in 23% of individuals with RTS and include horseshoe kidney, renal duplication, renal agenesis, renal dysplasia, hydrenephrosis, nephroliathiasis and vesicoureteral reflux. Symptomatology and treatment follow the general population management. Individuals with CREBBP and EP300 variants are equally affected and there is no known genotype–phenotype correlation.

The high prevalence of renal anomalies warrants at least one renal ultrasound and blood pressure measurement when the diagnosis of RTS has been made (online supplemental R31). If renal anomalies or elevated blood pressure are detected, consultation with a specialist ((paediatric) nephrologist and urologist) is recommended (online supplemental R32). Hypertension in children with RTS is rare but can occur, and is then caused by renal artery stenosis (Hennekam, unpublished observations).

Genitalia
The most common genital anomaly is unilateral or bilateral cryptorchidism, which occurs in 59% of men. All men should be checked by careful physical examination after diagnosis (online supplemental R33). Treatment is as in the general population following international guidelines. Other external anomalies occurring in less than 10% of individuals are hypospadias in both men and women, and fusion of labia minora, which can be treated as in the general population. Swallow scrotal formation is common in RTS and needs no treatment.

Uterine malformations have been reported rarely. Women may have hypermenorrhagia or metrorrhagia. A questionnaire survey among 76 women (online supplemental materials Menses Survey) yielded that 10 of them did not yet or did no longer menstruate, 21 of the remaining 66 (32%) used medication (typically contraceptives) because of menses problems, 19 of the 45 (42%) without this medication has metrorrhagia and 10 of 45 (22%) has menorrhagia. Contraceptives were invariably successful in treating the menses problems (online supplemental R34).

MUSCULOSKELETAL SYSTEM
Musculoskeletal anomalies in RTS vary widely. They are somewhat more frequent in individuals with CREBBP variants than in those with EP300 variants. Using the data from several large series of patients, major limb anomalies (CREBBP variants vs EP300 variants) are broad thumbs (343/360; 95% vs 51/81; 63%), radially-deviated thumbs (183/343; 53% vs 5/71; 7%) and broad halluxes (278/290; 96% vs 55/81; 68%). The broadness of the thumbs hardly ever causes problems, but the broadness of the halluxes may cause problems in walking or wearing shoes, especially if the halluces are medially deviated. In a minority of patients, surgical correction is needed. Several methods for surgical correction have been reported. However, often the deviated thumbs have good function and recurrence of the deviation after surgery is common. In our experience, a decision regarding surgery is best postponed until the function of the hands in the patient can be accurately evaluated, which typically can be done around 3–4 years of age. If surgery is indicated, it should be performed by a surgeon familiar with the procedure in RTS (online supplemental R35).

Other findings include limitation of mobility between the proximal and distal phalanx of the thumbs, broadness of distal phalanges of fingers, limited syndactyly, and rarely camptodactyly, but these do not require treatment.

Hypermobility in the hip, elbow, fingers and thumbs, knee and patella is common. In combination with other not well-known factors (muscular, bony, neurological), this may cause stiffness and the typical waddling gait in some adolescents and adults. A detailed evaluation of motor skills is indicated (online supplemental R36). Further studies describing gait problems in RTS are lacking.

Regular evaluation of the gait is indicated since patella dislocation and Perthes-like hip problems may need therapy (online supplemental R36). In particular, patella problems can cause major mobility challenges and, if untreated, can cause problems like genua valga and knee contractures. These issues may ultimately necessitate wheelchair use. Recurrent patella dislocation may require physical therapy, orthotics or surgical correction; although procedures are not always successful.

An emerging gait disturbance in older children and adolescents may be caused by an aseptic hip joint inflammation resembling Perthes disease, which occurs in 3% of patients, is often marked, and may take 2 or 3 years to resolve spontaneously. It may be difficult to distinguish this from slipped capital femoral epiphysis. Management is symptomatic.

Other uncommon limb problems such as congenital hip dislocation, tight heel cords and increased risk for fractures, should be treated as in the general population.

Scoliosis is reported in 34/184 (18%) of individuals with CREBBP variants and 15/78 (19%) of those with EP300 variants, and develops in late childhood and puberty. Treatment is as in the general population (online supplemental R37). Significant thoracic kyphosis and lumbar lordosis can occur and typically do not need treatment. Radiologically the spine may show changes resembling an early ankylosing spondylitis (M Bechterew) but progression into a true ankylosing spondylitis has not been reported. Other infrequent spine anomalies include instability of C1-C2, underdevelopment of the dens and cervical vertebral fusions, which should be managed as in the general population. Occult spine bifida is detected regularly but does not cause clinical manifestations and may be left untreated.

Children and adults have an increased fracture risk, and 8% of adults have osteoporosis indicating a potentially disturbed ossification in RTS (Simpson et al unpublished observations) (online supplemental R38). Clues for this abnormal ossification in radiographs of the upper spine have been reported.
the complete palate (sometimes submucous), the soft palate or only the uvula, which may or may not be accompanied by a cleft lip. A careful evaluation of the palate is indicated in every newborn or child with RTS (online supplemental R39). The treatment of clefting is as in the general population. Other, less frequent characteristics are a relatively large tongue, the bifid tip of the tongue, a short frenulum, and wide alveolar ridges.

Dental characteristics are almost universally present and may exist as abnormalities in tooth number (15–30%; hypodontia, hypodontia, mesiodens), structure (23–29%; enamel hypoplasia, discolouration), eruption (5%; neonatal teeth, persistence of primary teeth, delayed eruption), position (62–64%; malocclusion, malalignment, crowded teeth, crossbite) and abnormal tooth shape including talon cusps, a diagnostic hallmark for RTS. Talon cusps are accessory cusps on the lingual side of incisors. CREBBP and EP300 are strongly expressed in both incisors and molars and influence the formation of the secondary and (to a lesser extent) primary enamel knots, allowing, if mutated, for talon cusp formation in 27% of primary incisors and 70–92% of permanent (upper) incisors.

Sealing the fissures around the talon cusps may prevent caries. Treatment is only needed if it interferes with mouth closure and occlusion or leads to marked caries (online supplemental R40).

Dental anomalies may also be secondary, that is, difficulties in maintaining adequate oral health leading to caries and periodontal disease, and also to enamel demineralisation due to gastro-oesophageal reflux. Children and adults with RTS often demonstrate also anxieties when facing dental assessments and treatments, stressing the need for early intervention.

Informing parents and other caregivers of the importance of early adequate oral hygiene, and subsequent advice, is paramount. Regular dental evaluation and treatment, preferably by a dentist with experience in caring for individuals with special needs, can prevent further problems, and treatment may be aided with sedation or general anaesthesia, (online supplemental R41). Orthodontic assessments and treatments are as in the general population. However, some procedures may not be well tolerated and should be considered in close collaboration with the individual and family.

IMMUNOLOGY

Infections

Recurrent infections of organs or organ systems do not typically occur in RTS, except for respiratory infections (70% of children, <20% of adults), including otitis media. Explanations include microaspiration and gastro-oesophageal reflux, but dysfunction of the immune response may also contribute. B cell defects have been reported. If a child with RTS has recurrent unexplained infections, a baseline immune workup including complete blood count with differential, immunoglobulin (Ig) levels (IgG, IgA and IgM), vaccine titres and lymphocyte subsets with B-cell phenotyping should be performed (online supplemental R42). In lower airway infections microaspiration or gastro-oesophageal reflux should be considered (online supplemental R19). If the immune workup yields abnormal results, consultation with an immunologist is indicated (online supplemental R42). Although a reduction of T cell or specific T-cell subtypes has been found in some cases, combined immune defects such as viral or opportunistic infections, have not been reported and specific antiviral or antifungal prophylaxis is not indicated. Vaccination can be performed as in the general population, causing the typical level of protection (online supplemental R43).

Oncology

CREBBP and EP300 are involved in several basic cellular activities, such as DNA repair, growth, differentiation, apoptosis and tumour suppression. Early surveys suggested an increased frequency of malignancies in case reports on individuals with RTS. However, a more recent population-based study found no evidence of an increased risk for malignancies in individuals below 40 years of age. Data for older individuals are too limited to allow conclusions. Benign tumours, however, were more common: meningiomas and pilomatrixomas were present in 8% and 17% of molecularly-proven patients, respectively. Surveillance for malignancies below 40 years of age is not recommended; the value of additional surveillance at an older age remains uncertain, and these individuals should follow surveillance schemes according to national standards (online supplemental R44).

NEUROLOGY

Central nervous system anomalies

The most common intracranial malformations (74%) in individuals with RTS are corpus callosum-related malformations. Periventricular posterior white matter abnormalities (63%), cerebellar vermis malformations (58%) and small or absent olfactory bulb (32%) are also regularly observed.

Specific EEG findings also in individuals with RTS type 2, epilepsy is reported in 0–10%. In individuals with RTS type 2, epilepsy is not recommended, and EEGs should remain limited to individuals with RTS with epileptic seizures. Treatment and surveillance should follow national standards of care (online supplemental R46).

Epilepsy

Non-specific electroencephalogram (EEG) abnormalities are observed in around 58–76% of individuals with RTS2 but clinical epileptic manifestations are infrequent, ranging from 9% to 33%. In individuals with RTS type 2, epilepsy is reported in 0–10%. Specific EEG findings also in individuals without a history of seizures have been suggested, but have no consequences for medical care. Routine EEGs are therefore not recommended, and EEGs should remain limited to individuals with RTS with epileptic seizures. Treatment and surveillance should follow national standards of care (online supplemental R46).

NEURODEVELOPMENT

The early symptoms of delayed development are the delay in achieving basic motor skills (table 3). First words are typically spoken at 2 years of age, sentences of two words or three words at 4 years of age or later on, with a wide variability across individuals. IQ ranges from 25 to 79, non-verbal performance IQ generally being higher than verbal IQ. Individuals with a CREBBP variant typically have a moderate-to-severe intellectual disability (ID), while individuals with EP300 variants have mainly a mild ID and only rarely severe ID. There is no
correlation between the type and site of variants and cognitive abilities.1,11 Intellectual disability involves related impairments of cognitive function, learning attainment, expressive language, symbolic play and adaptive behaviour. The role of reduced neuronal histone acetylation in the aetiology of ID has been pointed out by mouse models of RTS showing deficits in long-term memory, but not in short-term memory on a variety of learning and memory tasks.13,14 Weaker memory impairments were found in Ep300 mutant mice136 in keeping with the milder ID of EP300- compared with CREBBP-mutated individuals. Consolidation of learnt information into long-term memories through stimuli-driven transcription is mainly imputed to CBP given its interaction with CREB, a key transcription factor involved in memory formation which diminished levels impair spatial memory,137 as observed in RTS children. Mice with Cbp mutation(s) disrupting CBP-CREB interaction, besides memory deficits, exhibit impaired motor skill learning,138 similar to the difficulties in planning and executing motor acts experienced by CREBBP-mutated patients.

Early assessment of cognitive abilities will benefit each child to access care earlier and for optimal stimulation of development (online supplemental R47). Non-verbal children may benefit from non-symbolic communication, such as non-speech vocalisation and gestures, which help them in their social interactions, and augmentative communication should be prioritised from early on, also in the preverbal stage (online supplemental R48). Early physiotherapy may enhance rehabilitation as well, focusing on the most weakened skills, which have been identified as those requiring a high level of visuomotor coordination.110 Early implementation and maintenance of communication strategies to catalyse preverbal and verbal language development and socialisation skills. Follow-up should include also repeated neuropsychological testing to ensure continuous optimal stimulation, especially at sensitive life phases (school entry, puberty, traumatic events, adulthood and ageing)42 (online supplemental R49).

BEHAVIOUR

Recommendations for clinical practice

Interventions for behaviours, cognition and emotion specifically for individuals with RTS are lacking. Applying strategies and intervention approaches designed for individuals with intellectual disability in general, as well as interventions for individuals with a diagnosis of autism, may be helpful (online supplemental table S4 summarises key recommendations).

Self-injurious and aggressive behaviour

The prevalences of self-injurious and aggressive behaviour vary markedly in children and adults with RTS (between 7–48% and 10–16%, respectively).13,18,19 These figures are similar to the prevalences in individuals with intellectual disability and autism in general.140 Aggressive behaviours may increase in older individuals.132,141 Our joint experience indicates that the self-injurious behaviour and aggression do not show specific characteristics. However, formal studies assessing individuals over time and describing specific topographies of behaviour using standardised measures, are lacking.

Emotions

Emotional outbursts, often severe and weekly, were noted in 7/31 children.139 However, a questionnaire study measuring ‘temper tantrums or hot temper’ found no differences between children with RTS and typically developing children.142 Emotional outbursts were reported in 5/13 adults with RTS,139 seemingly indicating an increase with age, as reported by others.132 On the Child Behaviour Checklist, 64.5% of individuals above 13 years of age and 27.5% of younger individuals were reported to be very anxious.141 The anxiety is not correlated with genotypes.59 For some anxiety subtypes, scores did not differ from children diagnosed with an anxiety disorder.143 Screening for anxiety using a questionnaire validated for individuals with intellectual disability will benefit many individuals with RTS (online supplemental R50). Subsequent interventions should follow best practice guidance for individuals with intellectual disability.

Repetitive behaviours

Repetitive behaviours in individuals with RTS include body, hand and object stereotypy, adherence to routines, repetitive phrases and repetitive questioning.59,142,144 Repetitive behaviour, in particular, repetitive questioning, has been associated with inhibitory control and working memory difficulties,143,144 which has led to the hypothesis that individuals may have difficulties suppressing questioning behaviour, and retaining information in their working memory.145,146 Co-occurrence of adherence to routines and temper outbursts in older individuals has led to the suggestion that executive function difficulties may contribute to these characteristics.142,146

Autism spectrum characteristics

Prevalence rates of autism range from 37–44% on standardised screening assessments.139,142 The estimates for individuals with a CREBBP variant have been higher (49%) compared with those with an EP300 variant (25%).3 Studies using direct assessments of children with a CREBBP variant and a severe intellectual disability, demonstrate areas of cognitive and socio-emotional differences similar to those in children with a diagnosis of autism matched for degree of disability.131 Therefore, families can make use of strategies designed for autism populations, specifically with respect to strategies for language delays, imitation and symbolic activities (online supplemental R51).

Caregivers need to be aware that most screening questionnaires use both repetitive behaviour and social behaviour in their scoring, and individuals with RTS may reach the cut-off for autism only because of their repetitive behaviour.

Social characteristics

Social behaviour is typically characterised by motivation to interact with others, and enhanced social skills,142 and ‘over-friendliness’
have been reported in >70% of individuals, while other studies using observational measures have suggested social motivation is aligned with typical development.

Parents have reported that their children are vulnerable to social exploitation, particularly as they age and gain independence. While social motivation is likely to be heightened or preserved, social understanding (eg, the ability to think about what another may be thinking) is a relative weakness. Individuals with RTS may benefit from learning appropriate skills to manage complex social situations, understand others’ intentions, and reduce impulsivity (online supplemental R52).

Self-regulation, impulsivity and overactivity
Distraction, impulsivity and overactivity have been noted from early descriptions of RTS. A short attention span was found in 76–90%, irrespective of the cognitive level. Studies yielded varying results regarding hyperactivity, and sometimes underactivity was noticed.

Increased pain threshold
Our joint experience indicates that many parents report their child has not shown evidence of pain or discomfort following a fall or an accident, even for gallstones, fractures, burns or other significant injuries and illnesses. Consequently, it is important not to underestimate subtle changes in behaviour. Medical professionals should be receptive to parent reports, and investigate proactively, even if the presence of a major health problem seems unlikely.

ADULT CARE
Over 90% of individuals with RTS reportedly survive to adulthood, and progress in diagnostics, knowledge and management abilities allows improved care for older individuals. Adults with RTS enjoy both social and occupational activities and show a varied experience of everyday life. A recently reported cohort of adults underscored the importance of continued management and follow-up. Half of all individuals required multispecialist follow-up and surgery during adulthood, usually more than once. Fortunately, significant morbidity in adulthood is not frequent. The adult natural history of RTS is defined by behavioural/psychiatric problems (83%), gastrointestinal problems (73%), skin and adnexa problems (65%), sleep problems (62%) and further concerns of high pain threshold, decreased mobility, hypersensitivity to noise and crowded places and vision difficulties or loss (approximately 50%).

The behavioural pattern remains broad but includes frequently rigid, repetitive and inflexible behaviours and emotional dysregulation (anxiety, aggression, frustration and/or a mood disorder) with reported age-dependent progression. Sleep problems show a consistent pattern of sleep apnoea, difficulty staying asleep and an increased need for sleep. Clinical concerns include gastrointestinal problems with the highest frequency of constipation and in much lower frequency, other problems including oesoinophilic oesophagitis. Retinal dysplasia increases with age, but does not cause severe loss of vision. Skin problems are variable but typically progressive, such as keloid formation, ingrowing fingernails and/or toenails (with infections) and poor wound healing. Hypertension, overweight, diabetes mellitus and cardiovascular problems do occur in adults but in a lower frequency compared with the general population. Treatment is as in the general population (online supplemental R53).

Data on fertility are limited but likely fertility is not impacted. Adults with RTS may be sexually active (25%). The risk to offspring is 50% with each pregnancy and familial recurrence has been reported. Thus, developmentally appropriate sexual education throughout the lifespan and especially at transition to adulthood is indicated (online supplemental R54). Contraceptive options should be discussed with the individual and family.

Reliable data on other adult problems such as dementia are not available.

CLINICAL TRIALS
CBP and p300 have multiple actions and functions, and clinical trials are aimed at decreasing or correcting abnormal functioning. Prenatally, variants in CREBBP/EP300 can cause malformations unamenable to postnatal change (online supplemental R55). Variants can also cause dysplasias, and these may still be influenced postnatally. CBP/p300 are the ‘master co-activators’ of transcription in humans, due to their involvement in many important pathways related to development and differentiation, and postnatal functions such as calcium signalling, nutrient metabolism, hypoxia and stress response. The latter may be influenced postnatally, thus obvious candidate dysfunctions are memory problems, behaviour, keloids and gastrointestinal problems (online supplemental R56).

Cognition
CREBBP/EP300 mutations cause epigenetic modifications that impact brain development and postnatal brain function of cbp+/cbp− mice. Histone deacetylases inhibitors (HDACi) lead to an increase in the acetylation in mice. The HDACi suberoylanilide hydroxamic acid and trichostatin A have been shown to influence neurological functioning and long-term memory in mice.

Inhibitors of phosphodiesterase 4 (PDE4) prevent the hydrolysis of cAMP-enhancing PKA-dependent signalling upstream of CREBBP. The PDE4 inhibitor rolipram abolishes the long-term memory defects of cbp+/cbp− mice. Rolipram is currently tested in Fragile X syndrome and Alzheimer’s disease (ClinicalTrials.gov Identifier: NCT03817684) that may be associated with reduced histone acetylation. If successful it is a candidate to be used in individuals with RTS as well.

The HDAC inhibitor sodium valproate can pass the blood-brain barrier. A monocentric, double-blind, randomised, phase 2 trial, primary endpoint long-term memory, investigated the efficiency of sodium valproate after 1 year of treatment (30 mg/kg/d) in 41 children with RTS (ClinicalTrials.gov NCT01619644). Results using subtests of a neuropsychological test battery specifically designed for memory evaluation did not demonstrate a significant difference between the verum and placebo groups. As a side effect, a slight amelioration of some motor functions was found, and a trial with sodium valproate using motor skills as a primary outcome should be considered.

Keloids
Keloids develop most likely following an inciting stimulus (environmental factor) in genetically predisposed individuals. The unremitting accumulation of thick fibres of collagen I and III in the extracellular matrix of connective tissue places keloids among fibrotic disorders. Keloids are unique to humans, there are no adequate animal models, and a high interlesional and intralesional heterogeneity impairs the comparison of in vitro models.
The principal cell type responsible for keloids is the myofibroblast derived from resident skin fibroblasts through transdifferentiation or pluripotent stem cells, but also keratinocytes play a distinct role based on their stemness signature. Fibroblasts from keloids overexpress transforming growth factor (TGF)-β1/2 and their receptors that interact with intracellular SMADs (Signaling Mothers Against Decapentaplegic), stimulate transcription of genes intervening in wound healing and cause persistent inflammation through continuous cell division, growth of extracellular matrix beyond the wound boundary, and abnormal vascularisation. Inhibition of the TGF-β1/2 signalling pathway is, therefore, the main target of keloids therapeutics. Indeed, the TGF-β receptor inhibitor LY2109761 has been shown to suppress the secretion of keloid matrix components and to slow down the proliferation of derived fibroblasts.

Within keloids, several pathways are dysregulated epigenetic modifications including DNA methylation, histone modification and non-coding RNAs. Reverting these epigenetic anomalies to those of normal skin may also lead to successful treatment. Mutated CBP/p300 causes abnormal histone acetylation which may cause the epigenetic signature of keloids in individuals with RTS to be different from that of keloids from individuals with other disorders. Much of the work on histone modifications on keloids has been focused on the use of the HDAC inhibitor trichostatin A. An increase in keloids of HDAC2 (and not of other HDACs), suggests the topical application of an HDAC2 inhibitor to be a potential treatment. CUDC-907 is an inhibitor of HDAC and also of the PI3K/AKT/mTOR pathway, and has been proposed as a candidate systemic drug.

Another approach is using upregulation of the mitochondrial oxidative stress response and protein processing in the endoplasmic reticulum (ER). Treatment with an inhibitor of ER stress tauroursodeoxycholic acid (TUDCA) reduced scar formation in the rabbit ear. The potential use in men is favoured by the clinical approval of TUDCA in cholestasis, and its effective inhibition of ER stress in fibropulmonary disease in mice. Single-cell RNA sequencing of keloid tissue has shown significant expansion of fibroblast and vascular endothelial cell subpopulations, responsible for the aberrant keloid fibrogenesis and angiogenesis. In fibroblasts TWIST1 and SMAD3 are top-upregulated genes and TWIST1 inhibition has been proposed as a therapeutic target (Liu 2021). Tumour-related pathways are activated in fibroblast and endothelial cell subpopulations, accounting for the excessive proliferation and resistance to apoptosis of keloids, and indicating the transferability and efficiency of medical therapies applied in tumours for the clinical treatment of keloids.
